Abstract The ectodermal dysplasias are a large group of hereditary disorders characterized by alterations of structures of ectodermal origin. Although some syndromes can have specific features, many of them share common clinical characteristics. Two main groups of ectodermal dysplasias can be distinguished. One group is characterized by aplasia or hypoplasia of ectodermal tissues, which fail to develop and differentiate because of a lack of reciprocal signaling between ectoderm and mesoderm, the other has palmoplantar keratoderma as its most striking feature, with additional manifestations when other highly specialized epithelia are also involved. In recent decades, the genes responsible for at least 30 different types of ectodermal dysplasia have been identified, throwing light on the pathogenic mechanisms involved and their correlation with clinical findings.

Displasias ectodérmicas: revisión clínica y molecular

Resumen Las displasias ectodérmicas son un amplio grupo de trastornos hereditarios que se caracterizan por la alteración de estructuras derivadas del ectodermo. Aunque algunos de estos síndromes poseen características específicas, determinados rasgos clínicos son comunes en muchos de ellos. De modo general, se diferencian 2 grupos de trastornos: uno caracterizado por la aplasia o hipoplasia de los derivados ectodérmicos, que fracasan en su desarrollo y diferenciación por la ausencia de señales recíprocas específicas entre ectodermo y mesénquima, y otro en el que la característica más llamativa es la queratodermia palmoplantar, que se presenta en asociación con otras manifestaciones cuando se afectan otros epitelios altamente especializados. En las últimas décadas se ha logrado identificar el gen responsable en al menos 30 entidades, permitiéndonos entender los mecanismos patogénicos y su correlación con la clínica.

Introduction

The ectoderm is one of the primitive embryonic components. At around the third week of development, it undergoes a subdivision into the neuroectoderm, the origin of the nervous system, and the ectoderm, which will envelop the entire embryonic surface and form the epidermis, epidermal appendages, and tooth enamel. The ectoderm therefore gives rise not only to hair, teeth, nails, and sweat glands, but also to the central nervous system, peripheral nervous system, eyes, ears, and nose, as well as the eccrine, mammary, and pituitary glands. During development, the ectoderm undergoes complex interactions with the mesoderm, so ectodermal disorders may lead to abnormalities in mesodermal structures such as the musculoskeletal and genitourinary systems.

Ectodermal dysplasias (EDs) are a heterogenous group of hereditary disorders characterized by certain shared structural and functional abnormalities in tissues derived from the ectoderm. Most of these diseases are also associated with an abnormal development of structures derived from the mesoderm and, occasionally, mental retardation. They are considered rare conditions, with an estimated incidence of 7 cases per 10,000 births. They can be transmitted by any of the possible Mendelian inheritance patterns, and although many share certain clinical characteristics, some syndromes have specific clinical findings. To date, approximately 200 such conditions are known, and the causative gene mutation has been identified in around 30. Mutations in only 4 genes (EDA1, EDAR, EDARADD, and WNT10A) are responsible for most cases of ED.

Historical Perspective

The first descriptions of clinical cases that might correspond to what we would now classify as ED date from 1792. In 1848, Thurman defined anhidrotic ectodermal dysplasia (also known as hypohidrotic ectodermal dysplasia [HED]) as a condition in its own right. Subsequently, similar cases were reported, such as the one presented by Weddernhorn and published in 1875 by the naturalist Charles Darwin: "I may give an analogous case, communicated to me by Mr. W. Weddenburn, of a Hindoo family in Scinde, in which ten men, in the course of four generations, were furnished, in both jaws taken together, with only four small and weak incisor teeth and with eight posterior molars. The men thus affected have very little hair on the body, and become bald early in life. They also suffer much during hot weather from excessive dryness of the skin. It is remarkable that no instance has occurred of a daughter being affected...though the daughters in the above family are never affected, they transmit the tendency to their sons: and no case has occurred of a son transmitting it to his sons. The affection thus appears only in alternate generations, or after long intervals." The above case described by Darwin corresponds to what we would describe today as X-linked HED, a term coined by Weech in 1929.

Classification of Ectodermal Dysplasias

The classification of EDs is complex, and classification systems have come and gone in an attempt to accommodate clinical and genetic data. Biomolecular findings have enabled the identification of the causative mutations that become manifest through 2 broad pathogenic mechanisms, associated with specific clinical features. Using these mechanisms as a starting point, in 2009, Priolo established a clinical-functional classification, which will form the basis for this review. The author proposed the definition of 2 groups of disorders (Fig. 1).

Group 1

Group 1 corresponds to disorders in which defective interaction between the ectoderm and the mesenchyme is apparent. Two pathophysiologic mechanisms have been identified:

2. Regulatory changes in transcription and/or expression of genes such as p63, DLX3, MSX1, EVC2, and EVC.

The resulting clinical phenotype is hypoplasia or aplasia of structures derived from the ectoderm. Development and differentiation of these structures fail due to the absence of specific reciprocal signals between the ectoderm and the mesenchyme (Table 1).

Group 2

Group 2 corresponds to disorders in which there is abnormal function of a structural protein in the cell membrane. Examples of structural proteins include nectin 1, connexins, and plakophilin, whose role in adhesion and cell-cell communication is essential for maintaining tissue homeostasis and controlling cell growth, development, and response to different stimuli.

Clinically, these disorders are mainly characterized by skin abnormalities such as palmoplantar keratoderma, with or without involvement of highly differentiated epithelia associated with deafness or retinal dystrophy (Table 2).

Group 1

Changes in the Signaling Pathways That Modulate NF-κB Activity

Ectodysplasin/EDAR/EDARADD Pathway
EDA, which consists of 391 amino acids, is a type 2 transmembrane protein belonging to the tumor necrosis factor (TNF) family. The most biologically important isoforms of EDA are EDA-A1 and EDA-A2. EDA-A1 binds to the EDA receptor (EDAR), whereas EDA-A2 binds to the X-linked EDAR A2 ligand (Fig. 2). EDAR is a type 1 transmembrane protein...
that consists of 448 amino acids and belongs to the TNF receptor superfamily. It has an extracellular region, a trans-
membrane region, and a death domain in its intracellular
region. A death domain is a protein interaction module
that interacts with the death domains of other proteins,
thereby triggering metabolic cascades that are often im-
plied in regulating apoptosis and inflammation through
the NF-κB cascade. The extracellular domain of EDAR is
essential for binding to EDA-A1, whereas the death domain
on the intracellular region plays an important role in the
initiation of apoptotic transduction signals. The EDAR death
domain has an associated death domain protein (EDARADD),
which contains a 208 amino-acid sequence. The integrity
of the death domains of both proteins is thus vital for
their interaction and a normal regulation of embryonic
morphogenesis. Therefore, the EDA-mediated signaling
pathway is essential for appropriate organ development
and ectoderm-derived structures, such as hair, nails, pitu-
itary gland, mammary glands, sweat glands, nose, eyes, and
tooth enamel.

The EDAR gene, which has 12 exons, is located on chro-
mosome 2 (locus 2q11-q13) and encodes the receptor
for EDA-A1 (EDAR). To date, at least 41 EDAR mutations
have been described. Most of these involve exon 12, which

Figure 1 Pathogenic mechanisms in ectodermal dysplasias. In group 1, there is an abnormal interaction between the ectoderm
and the mesenchyme, thereby impeding correct differentiation of the epidermal derivatives, which are hypoplastic or aplastic. In
group 2, the interaction between the ectoderm and mesenchyme is normal, and the epidermal derivatives differentiate normally,
but tissue homeostasis and growth are abnormal, so dysplasia is present in the ectodermal derivatives. Adapted from Priolo.

Figure 2 Ectodysplasin-EDAR-EDARADD pathway. The ectodysplasin-A (EDA) protein binds to an ectodysplasin-A receptor
(EDAR), located in the extracellular region of EDAR. EDAR has an extracellular region, a transmembrane region, and a death domain in its intracellular region. This death domain binds to the death domain of EDAR-associated death domain
(EDARADD). Adapted from Lu et al.

encodes the C-terminal region where the death domain is located.34 Some of these mutations have been reported in Spanish patients.25,36 The EDARADD gene, located on chromosome 1 (locus 1q-42-q43), encodes EDARADD, which is implicated in several diseases of autosomal recessive and dominant inheritance.17,27 Finally, certain mutations in the WNT10A gene, whose product is a member of the Wnt signaling pathway and implicated in embryonic development and cell differentiation, as well as in certain physiologic processes in adults and certain cancers, have been shown to give rise to several forms of ED of autosomal inheritance, such as HED or odonto-onycho-dermal dysplasia.3

**X-linked HED.** Also known as Christ-Siemens-Touraine syndrome, X-linked HED is the most frequent form of ED, with an incidence of approximately 1 case per 100,000 births.28 Given the X-linked inheritance, affected males show all or most of the typical characteristics of the disease, while female carriers show only partial manifestations. There is no genotype-phenotype relationship, and the phenotype can vary greatly among different families and within the same family group.29 X-linked HED occurs as a result of mutations in the ED1 gene, also known as EDA.30 This gene is located on the long arm of the X chromosome (locus Xq12-q13) and encodes the EDA protein. More than 204 different ED1 mutations have been identified.34 Although a wide range
of deletions and insertions have been reported, just 1 mutation accounts for 80% of the cases. Recently, a Spanish group has identified a family with a previously unreported mutation in this gene.

The distinctive clinical features include skin, tooth, and sweating abnormalities. In the neonate, the characteristic abnormalities are not especially notable, and so diagnosis in the first days of life is difficult. Up to 70% of boys with X-linked HED show skin desquamation during the neonatal period. This finding is also relatively common among female carriers. Cases of presentation as collodion baby have been reported. Alopecia is usually the first notable characteristic, although alopecia universalis is rare (Fig. 3). During childhood, most patients have sparse, fine, blond hair which darkens and thickens as the individuals get older. The eyebrows and beard are also sparse, but the eyelashes and armpit and pubic hair can be normal. Other body hair is also sparse or even absent. In some patients, hair shaft abnormalities may be present, though this finding is not specific for X-linked HED. Tooth abnormalities may become apparent during lactation as hypoplasia of the alveolar crests (Fig. 4). The number of missing and malformed teeth varies greatly between families and within the same family and there are also substantial variations between sexes. Morphologic variations are more evident in the anterior teeth. The most common type of affected tooth has an abnormal crown and takes on a cone or peg shape (Fig. 5). An X-ray will usually reveal taurodontism, an abnormality mainly of the molars characterized by a shortening of the root although the total height of the tooth is unchanged, yielding a prismatic form. The ability to sweat is reduced or absent, and so patients are predisposed to developing hyperthermia.

**Figure 3** X-linked hypohidrotic ectodermal dysplasia with alopecia universalis of the scalp, eyebrows, and eyelashes in an infant. Also of note is the frontal bulging, lip eversion, and discrete perioral eczematiform lesions.

**Figure 4** Alveolar hypoplasia in an infant with X-linked hypohidrotic ectodermal dysplasia.
with physical exercise or high ambient temperatures. More than 90% of children have recurrent fever spikes with no apparent cause during the first year of life. Febrile seizures occur in approximately 6% of children with X-linked HED. Sweat disorders make a substantial contribution to the morbidity and mortality associated with X-linked HED; thus the mental retardation reported in between 30% and 50% of some series could be due to the damage caused by prolonged fever and febrile seizures. Although a genotype-phenotype correlation is apparent in terms of extent of sweat gland dysfunction, the risk of hyperthermia cannot be predicted and there is no correlation with morbidity and mortality.

In the full syndrome, patients have characteristic facies, with a prominent frontal bone and chin, sunken nasal bridge, thick and everted lips, large ears, and a broad and high maxillary bone. Most abnormalities in craniofacial morphology can be attributed to the absence of teeth, although some authors have suggested that changes in embryonic morphogenesis could also be responsible. In addition to the typical characteristics, from childhood onwards, patients usually develop a dry, thin, shiny skin, periocular hyperpigmentation and fine periorcular wrinkles giving the appearance of premature aging (Fig. 6), as well as small papular lesions reminiscent of sebaceous hyperplasia. Up to two-thirds of patients have atopic eczema, which can be difficult to control. Palmoplantar keratoderma is rare in X-linked HED, although it is often found in hidrotic ectodermal dysplasia and Clouston syndrome. The nails can be normal or fragile, but they are not usually especially dystrophic.

Abnormalities in the mucosal glands can cause very thick nasal secretions that predispose patients to the development of respiratory tract infections. The decreased salivary secretion could, according to some authors, increase the risk of tooth decay and oral fungal infections, and also hinder food ingestion and speech. The reduction or absence of meibomian glands and Moll and Zeiss gland dysfunction can lead to the development of eyelid abnormalities from the second decade of life. Thick cerumen in the ears may lead to obstruction of the external auditory canal and thus hypoacusia. Mammary glands may be hypoplastic or even show complete agenesis, but sexual development is usually normal.

Female carriers of an ED1 mutation may be asymptomatic or show mild or moderate clinical manifestations. A characteristic sign suggestive of the disease is present in 70%. The most frequent manifestations are tooth abnormalities, mild hypohidrosis, and differing degrees of hypotrichosis. A patchy distribution of body hair can be found, with somewhat depressed alopecic and xerotic areas in a Blaschkoid distribution alternating with areas of normal skin. The affected areas are more evident with tanning and during childhood. In some carriers, a radial shift in the distal phalange of the index finger has been reported.

**HED of autosomal transmission.** The autosomal forms of HED, which are much less frequent than the X-linked forms, can follow a dominant or recessive inheritance, and are caused in most cases by mutations in the EDAR or EDARADD genes. Patients with autosomal transmitted HED are clinically indistinguishable from male patients with X-linked HED. In general, patients with the recessive form have more severe abnormalities, whereas the clinical spectrum of the dominant forms is variable and at times very mild, with clinical manifestations similar to those observed in X-linked HED carriers. In recessive transmission, heterozygous carriers are clinically indistinguishable from individuals with normal genotypes. The genetic heterogeneity of HED and the clinical similarity between patients with different transmission modes can be explained by the involvement of ectodysplasin, EDAR, and EDARADD in the same pathway, as activation of NF-κB by ectodysplasin is necessary for the initiation, formation, and differentiation of ectodermal derivatives.
Completely affected individuals, such as those with the full syndrome, but it can be difficult in partial cases and in carriers of the disease. In such cases, it is necessary to perform additional tests to determine decreased sweating or a decreased number of eccrine glands.

The Minor test or iodide-starch test is very useful for confirming the absence of sweating, which is generalized in affected individuals and patchy in female carriers, who have normally functioning eccrine glands alternating with eccrine glands with reduced function in areas with a Blaschkoïd distribution (Fig. 7). Examination of large areas of the body, such as the back, can more readily reveal this mosaic distribution. Moreover, such an examination is useful for differentiating between X-linked HED carriers and females affected by autosomally transmitted HED, in whom the function of the sweat glands is almost completely absent. Other methods for assessing sweating include iontophoresis after applying pilocarpine to the forearm, sweat pore count, and measurement of skin conductance or temperature; such methods are useful for screening but are less sensitive in patients with residual gland function. Skin biopsy is not normally essential for confirmation, but the lack of eccrine glands has a positive predictive value and diagnostic specificity of 100%. Molecular analysis is the only way of determining which gene is involved, detecting carriers, and confirming the type of inheritance. This information is vital for genetic counseling.

Prognosis and treatment. For many years, the mortality rate in children with X-linked HED was thought to be around 30% during early childhood, but today it is known to be around 13%. Complications appear in the first years of life as a result of hyperthermia and respiratory infections, but after childhood, life expectancy is normal. Education of the patients and their families is essential to prevent hyperthermia. Physical activity does not need to be completely avoided, but patients and their families should be aware that high body temperature can cause symptoms such as headache, nausea and vomiting, dizziness, excessive tiredness, and muscle cramps. They should also be made familiar with techniques for reducing body temperature (immersion in water, air conditioning, cold drinks, use of refrigerated devices, etc.). Water sports are ideal for these patients.

There is no treatment for the associated skin disorders or periorificial hyperpigmentation, and outbreaks of atopic dermatitis may be difficult to treat. Some authors have suggested these patients have an increased risk of melanoma, and so a full physical examination is recommended once a year. Management of children with HED also includes early dental care to prevent maxillary hypoplasia and gum atrophy, which if severe may hinder chewing and language development in addition to being a notable aesthetic problem. Other specialists may also be involved in the care of these patients, for example, ear-nose-throat specialists when nasal and cerumen secretion is a problem, ophthalmologists when eye dryness or problems with the eyelids are present, pulmonologists in the event of respiratory tract infections and, in some case, psychologists. Gene therapy with recombinant EDA is still in the experimental phase, but it may offer hope for these patients in the future. Finally, as is the case in many other genetic diseases, patients diagnosed with HED will need continuous updates about their disease and socioeconomic support. We therefore recommend that patients contact the Spanish Association of Patients With HED (abbreviated as AADE in Spanish): http://www.displasiaectodermica.org.

NF-κB Signaling Pathway
NF-κB is a transcription factor that regulates the expression of multiple genes implicated in immune and inflammatory responses, reaction to stress, cell adhesion, and protection against apoptosis. In most cells, NF-κB is kept in an inactive state through cytoplasmic sequestration by the NF-κB inhibitory protein (IκB). Several stimuli, such as interleukin (IL)1, TNF-α, lipopolysaccharides (bacterial endotoxins), and double-stranded RNA (from viral infections) lead to activation of the cell membrane receptors of the TNF family, such as EDAR and the receptor activator of NF-κB (RANK). Activation of these receptors leads to degradation of IκB through the IκB kinase (IκK) complex, which is phosphorylated to form IκB, so allowing NF-κB translocation to the nucleus. In the nucleus, the NF-κB induces genetic transcription, triggering critical inflammatory and immune responses in the development of T and B cells and in osteoclast function and growth of epidermal cells. The IκK complex consists of at least 3 subunits: IκK1/IκKa, IκK2/IκKβ, and NEMO/IκKBγ (essential modulator of NF-κB). IκK1 and IκK2 act as catalytic subunits, whereas NEMO is a structural and regulatory subunit, essential for the complex to function as a unit. If NEMO is not present, NF-κB shows no response to stimuli, as NEMO is the main molecule that provides this signaling from the cytoplasm nucleus (Fig. 8).

Both activation and inhibition of NF-κB have been associated with the development of inflammatory skin conditions. Mutations in 2 genes, NEMO and IκBα, have been shown to give rise to a heterogeneous group of genetic disorders that include incontinentia pigmenti; X-linked HED with immune deficiency; osteopetrosis, lymphedema, and HED with immune deficiency; and autosomal dominant HED with immunodeficiency.
Incontinentia pigmenti. Incontinentia pigmenti is a rare disease whose exact prevalence is not known. It is caused by mutations in the NEMO gene, which is located on the X chromosome (locus Xq28). Approximately 97% of the patients are female as the condition causes intrauterine death in most males. Most female patients survive due to the selective elimination of cells that express the X chromosome with the mutation. The clinical expression of the disease is variable. Nevertheless, male patients can also have the condition in the case of somatic mosaicism or XXX trisomy.

The skin manifestations are the most striking but not the most serious. They are present in almost all patients, with onset during the neonatal period. The lesions are distributed along the Blaschko lines and are usually divided into 4 stages: vesicular, verrucous, hyperpigmented, and atrophic (Fig. 9). The first stages may go unnoticed, and the patients only show mild hyperpigmented lesions that are not detected until the patient gives birth to an affected daughter. Some women might not even show any clinical manifestations despite being carriers of the mutation. The most important clinical problems are vision disorders and neurological deficits, but fortunately, these are less common than the skin manifestations, appearing in 40% and 30% of the patients, respectively. In addition, patients may show other problems such as alopecia, tooth abnormalities (cone or peg-shaped teeth, hypodontia, or anodontia), and nail dystrophy. Given that a detailed review of this disorder is beyond the scope of this article, we refer the interested reader to other literature sources.

X-Linked HED With Immune Deficiency. X-linked hypohidrotic ectodermal dysplasia with immunodeficiency is a rare X-linked recessive disorder that affects mainly males, although some cases have been reported in female patients. The estimated incidence is 1 case per 250,000 newborns. Most patients show small deletions or non-sense mutations in the zinc finger domain (zinc-bound region that allows interaction with other molecules) of NEMO that do not lead to complete loss of NF-κB activation, as occurs with incontinentia pigmenti, but rather an altered or reduced function of the NF-κB pathway.

Both males and females with X-linked HED with immunodeficiency have mothers with skin lesions reminiscent of incontinentia pigmenti, as well as variable manifestations of HED, including cone-shaped teeth. Some patients have prominent superficial veins. A skin phenotype has also been described with initial involvement of intertriginous areas. The lesions, which have a seborrheic appearance, progress to erythroderma and are reminiscent of lesions in patients with congenital immunodeficiencies such as combined severe immunodeficiency or Omenn syndrome. In some cases, incontinentia pigmenti lesions have been observed, thereby illustrating the complexity and overlap between different diseases derived from NEMO mutations. Patients with X-linked HED with immunodeficiency have a poor inflammatory response caused by abnormalities in cell response to proinflammatory cytokines (IL-1β, IL-18, and TNF-α). The most frequently reported immunodeficiency is dysgammaglobulinemia, with normal or low IgG levels, although elevated IgA, IgM, and IgE levels can also
be observed. In addition, there have been reports of defects in natural killer (NK) cells, decreased TNF and IL-12 production, abnormal immune response to polysaccharide stimuli with the inability to form specific antibodies to Streptococcus pneumoniae, and a delayed or absent production of isohemaglutinins. Thus, in addition to the characteristic HED phenotype, these patients have serious and recurrent bacterial infections in the lower respiratory tract, skin, soft tissues, bones, gastrointestinal tract, and meninges. The pathogens are usually pyogenic bacteria such as S. pneumoniae, Haemophilus influenzae, Staphylococcus aureus, Klebsiella, Salmonella, and Pseudomonas species, as well as mycobacteria, cytomegalovirus, herpes simplex virus, and Pneumocystis jiroveci. Although the infectious complications are generally considered the most life-threatening, defects in NF-κB signaling also increase the risk of inflammatory diseases and inflammatory colitis in particular.

Female carriers have a range of manifestations, from normal teeth to mild hypodontia or cone-shaped teeth. There has been an anecdotal report of 2 women with mottled skin pigmentation.

Dominant X-linked HED with immunodeficiency. In cases of dominant transmission, the patients have an IκBα mutation that prevents phosphorylation and degradation of the IκBα protein resulting in abnormal activation of NF-κB. These patients have the classic characteristics of HED, along with T-cell immunodeficiency, giving rise to recurrent infections and immune deficiencies. Although patients with NEMO and IκBα mutations share certain clinical manifestations, their immunologic phenotypes are different. These patients have marked T-cell deficiency characterized by loss of CD45RO+ cells and abnormal T-cell receptor-mediated stimulation of lymphocytes when studied in vitro. They are unable to respond to TNF-α stimulation, and have abnormal antibody production and greater susceptibility to infections by gram-positive and gram-negative bacteria, as in patients with NEMO mutations. However, these patients have normal NK cell activity, and so are not susceptible to mycobacterial infections. It seems that hypomorphic mutations in the stop codon of IκBα could produce a small change in NF-κB activation, giving rise to less severe immunodeficiency.

Mutations in the stop codon of the NEMO gene yield osteopetrosis, lymphedema, and HED with immunodeficiency. As with children with X-linked HED with immunodeficiency, these patients have HED skin manifestations, may have skin lesions similar to those of incontinentia pigmenti, and have an abnormal inflammatory response. Immunodeficiency is particularly severe, and so these patients experience unusual, aggressive, and often fatal infections from early childhood. The distinctive clinical characteristics are osteopetrosis and lymphedema, which are thought to be due to abnormal signaling involving RANK, a receptor of the TNF family present in osteoclast progenitor cells. Differentiation and function of these 2 types of cells depends on NF-κB. In these patients, osteoclast differentiation is abolished or severely reduced, and so the bones formed are dense but fragile. The NEMO gene encodes the vascular endothelial growth factor receptor 3, an activator of the NF-κB pathway. Such a NEMO mutation would be associated with interference in this pathway, giving rise to lymphatic vessel dysfunction and characteristic lymphedema.

Female carriers of a hypomorphic mutation in the NEMO gene may be asymptomatic or have several manifestations of incontinentia pigmentaria.

Figure 9 Different clinical aspects of incontinentia pigmenti. A, Vesicular phase in a neonate. B, Linear hyperpigmented lesions on the legs in a later stage. C, Dental agenesis and presence of cone-shaped teeth. D, Nail dystrophy, with trachyonychia and pitting of the nail plate.
Diagnosis of NEMO/IKKα-derived disorders. Mutations in the NEMO gene should be considered in children with refractory extensive seborrheic or atopic dermatitis, particularly when the facial characteristics of HED are present or the mother has a history of incontinentia pigmenti. A biopsy of the skin lesions is recommended in patients with HED with immunodeficiency, as they can develop similar lesions to incontinentia pigmenti after childhood.

Treatment. The management of patients with HED manifestations is similar to that presented in the preceding section. Treatment of immunodeficiency may include immune therapies and an aggressive approach to infections, including prophylaxis against gram-positive and gram-negative bacteria, mycobacteria, herpes simplex virus, and Pneumocystis jiroveci. Even with such an approach, morbidity and mortality are high. Hematopoietic cell transplantation offers the possibility of immune reconstitution, but it brings with it the inherent risks of immunosuppression.

Little has been published on the subject. Allogeneic transplantation of hematopoietic progenitors could correct the immunodeficiency associated with diseases due to NEMO or IKKα mutation, but the causative mutations do not exclusively affect the hematopoietic system, and so constitutional manifestations not related to immunodeficiency are not corrected by transplantation. Inflammatory colitis might therefore even worsen on correcting immunodeficiency.

Changes in the Transcription and/or Expression of Regulators of Certain Genes

Disorders Derived From p63 Mutations

The p63 gene, also known as TP63 (tumor protein 63), is located on chromosome 3 (locus 3q27) and encodes the transcription factor p63, involved in ectodermal development. The regions of greatest biological importance are the DNA binding domain (a region that allows transactivation through binding of p63 to DNA), the sterile alpha motif (SAM), which is thought to participate in protein-protein interactions, and the transactivation inhibition domain (TID), which is located next to the SAM domain and could be involved in balancing the effects of different isoforms of TP63. The p63 protein is expressed very early during embryogenesis and plays an essential role in inducing epithelial differentiation and proliferation and in other processes including facial and limb development. Lack of expression of this protein during early development of ectodermal structures might block a chain of interactions between the epithelium and the mesenchyme, thereby interfering in normal morphogenesis. In addition, p63 regulates expression of P-cadherin, a critical regulator of hair development.

Heterozygous mutations in the p63 gene are responsible for at least 6 different syndromes that combine ED, orofacial clefts, and limb malformations. The ectrodactyly-ectodermal dysplasia-cleft lip/palate syndrome (EEC) syndrome is the prototype syndrome. Other syndromes include ankyloblepharon-ectodermal dysplasia-cleft lip/palate (AEC) syndrome, limb-mammary syndrome, acro-dermato-ungual-lacrimal-tooth (ADULT) syndrome, Rapp-Hodgkin syndrome, and split-hand/foot malformation. All these syndromes present at least 1 of the key characteristics of EEC syndrome.

Figure 10 Anodontia and dental dysgenesis in a patient with ectrodactyly-ectodermal dysplasia-cleft lip/palate syndrome.
to tooth decay due to defective enamel and changes in the salivary gland function. Orofacial cleft is common and may be accompanied by maxillary and malar hypoplasia. Tear duct stenosis contributes to keratitis, which is sometimes associated with photophobia. Urogenital and anogenital abnormalities (micropenis, hypospadias, vaginal septum, and female genital hypoplasia), hypothalamic-hypophyseal insufficiency, thymic hypoplasia, and mental retardation may also be present. Isolated cases have been reported of an association with white sponge nevus, as well as micrognathia, cleft soft palate, and glosptosis (Pierre Robin sequence), but the relevance of this association is not known.

Prenatal ultrasound diagnosis is an important aspect of diagnosis of EEC syndrome, not only because ectrodactyly and cleft lip/palate may alert the physician, but also because severe associated genitourinary abnormalities can be detected.

**Ankyloblepharon-ectodermal dysplasia-cleft lip/palate syndrome.** The AEC disorder follows an autosomal dominant transmission pattern and results from non-sense mutations in the SAM domain of protein p63, implicated in the interaction with other proteins participating in the regulation of transcription and development of skin appendages. The characteristic clinical triad consists of ankyloblepharon, ectodermal defects, and cleft lip/palate (Fig. 12). Ankyloblepharon is a condition in which fibrous bands between the eyelids prevent these from opening or moving normally. The ectodermal abnormalities are similar to those of other EDs. In addition to these abnormalities, skin erosions can be observed in the scalp, head, neck, skin folds, palms, and soles. The erosions heal poorly and tend to become superinfected. On the upper part of the trunk, they heal to leave residual scarring of a cribriform, reticular, stellate, or punctate pattern. Although the exact reasons for the erosions and delayed wound healing are not well known, a contributing factor could be the role of protein p63 in the formation of basal cells and epidermal differentiation. At birth, patients may present manifestations such as erosive lesions, congenital erythroderma, ichthyosiform scaling, and even collodion membrane which may lead to an initial suspicion of epidermolysis bullosa or a keratinization disorder. Changes in pigmentation (hyperpigmentation or hypopigmentation) are also frequent (Fig. 13). Reticular hyperpigmentation, which becomes more accentuated with age, can be observed in the large skin folds, whereas characteristic hypopigmentation, which improves as the patient gets older, may be present around the eyes giving a mask-like appearance. Almost all patients have sweating disorders. The extent of alopecia is variable and does not seem to be related to age or severity of prior erosions in the scalp. Hair may be thick, wiry, fragile, or matt, and have variable or even 2-tone pigmentation (pigmented and pale hairs). Hair shaft abnormalities, such as pili annulati, pili torti, and pili canaliculi, and irregular indentation may be present. Nail involvement is also variable (Fig. 14) and ranges from complete anonychia to mild scaling of the nail plate. Other skin abnormalities occasionally reported include absence of
dermatoglyphs, palmoplantar hyperkeratosis, punctate keratoderma, hyperlinearity, and hyperkeratosis on the elbows and knees.\textsuperscript{111}

Facial dysmorphia includes, in addition to cleft palate and lips, small or malformed ears, maxillary hypoplasia, lack of permanent teeth, and decreased length of the eyelid skin crease. Failure to thrive, syndactyly, nasolacrimal atresia, recurrent otitis media, hearing loss, and hypoplasias are also common.\textsuperscript{96} Some individuals may experience neutropenia of unknown origin and have recurrent skin and ear infections, which may progress to bacteriemia and sepsis.\textsuperscript{96}

AEC syndrome should be suspected in any neonate with erythroderma and cleft lip/palate, particularly when other skin manifestations are present, such as erosions in the scalp or skin, although ankyloblepharon is not always present. Skin biopsy, although not very specific, shows mild hyperkeratosis, epidermal atrophy, basal pigmentation, and/or incontinencia pigmenti, and a prominent superficial vascular plexus with mild perivascular infiltrate consisting mainly of lymphocytes.\textsuperscript{112}

The first objective of treatment is to prevent skin erosions, and so energetic cleansing of the skin should be avoided. Secondary wound infection can be hard to treat, and so extensive daily hygiene and application of antiseptics to the erosions are recommended. The administration of antibiotics for long periods would only seem to provide a minimal or temporal improvement in the lesions. Some authors have suggested that the use of corticosteroids\textsuperscript{113,114} or low doses of doxycycline\textsuperscript{115} may be useful for reducing inflammation and improving healing, but the risk of side effects should be taken into consideration. Looking to the future, other therapeutic strategies, such as gene therapy and use of epidermal stem cells to regenerate affected skin, are under investigation.\textsuperscript{111}

\textbf{Acro-dermo-ungual-lacrimal-tooth syndrome.} EEC and ADULT syndromes are considered allelic disorders with overlapping clinical characteristics, such as ectodermal, limb, and tooth abnormalities. The main difference lies in the absence of orofacial cleft from ADULT syndrome.\textsuperscript{116} ADULT syndrome arises through mutations that affect the TID domain, implicated in transactivation of the p63 gene.\textsuperscript{117} To date, 5 mutations in this gene have been reported; 2 of these have also been identified in patients with EEC syndrome.\textsuperscript{118}

\textbf{Limb-mammary syndrome.} The limb-mammary syndrome, with an autosomal dominant inheritance, is caused by mutations in the SAM and TID domains of the p63 gene.\textsuperscript{119} Its clinical characteristics overlap with those of EEC, AEC, ADULT and Rapp-Hodgkin syndromes, as well as with ulnar-mammary syndrome (caused by mutations in the TBX3 gene at locus 12q24.1).\textsuperscript{120} The syndrome is characterized by ectodactyly, hypoplasia of the mammary glands and nipples, cleft palate (without a cleft lip), and the absence of skin or hair abnormalities. Other manifestations include lacrimal duct stenosis, hearing loss, urogenital abnormalities, nose dysplasia, hypohidrosis, hypodontia, and gonadal dysplasia.\textsuperscript{96,120}

Differentiation between limb-mammary syndrome and EEC syndrome is based on 3 findings:\textsuperscript{120} hypoplasia of the mammary glands and nipples, present in all cases of limb-mammary syndrome but only occasionally in EEC syndrome; hair and skin abnormalities, absent in patients with limb-mammary syndrome; and cleft lip, present only in patients with EEC syndrome.

\textbf{Rapp-Hodgkin syndrome.} Rapp-Hodgkin syndrome is a disorder of autosomal dominant transmission,\textsuperscript{121} produced by mutations that, like in AEC syndrome, affect the SAM domain, thereby explaining the considerable clinical and molecular overlap between the 2 syndromes.\textsuperscript{96,122} Some authors consider these 2 syndromes as the same disorder.\textsuperscript{121-127}

\textbf{Tricho-dento-osseus syndrome} The tricho-dento-osseus syndrome is a condition of autosomal dominant transmission caused by different mutations in the DLX3 gene, located on chromosome 17 (locus 17q21). This gene, which is also responsible for imperfect amelogenesis, encodes the DLX3 protein,\textsuperscript{128} which is expressed during embryogenesis and which participates in the differentiation of tissue derived from the ectoderm, bone tissue, and cartilaginous tissue.\textsuperscript{129} The clinical manifestations are variable and include abnormalities in tooth enamel, nail abnormalities, blond curly hair, sclerosis and thickening of cranial bones, radiographic abnormalities such as hypocalcification, and taurodontism.\textsuperscript{130}

\textbf{Witkop Syndrome} Witkop syndrome, an autosomal dominant condition also known as the tooth and nail syndrome and nail dysgenesis and hypodontia, is caused by a mutation in the MSX1 gene, located on chromosome 4 (locus 4p16.1). The MSX1 gene participates in the formation of certain teeth (premolars, first molars, and third molars) and nails, by determining the thickness and integrity of the nail plate.\textsuperscript{131} Typical clinical characteristics are nail dysplasia and hypodontia, although the clinical manifestations are very varied. In some cases, hair abnormalities (fine or thick hair) have been reported; though most individuals have normal hair and sweat gland function.\textsuperscript{132}

\textbf{Ellis-van Creveld Syndrome} Ellis-van Creveld syndrome follows an autosomal recessive transmission pattern and is caused by mutations in the EVC or EVC2 genes; the clinical phenotype is the same for both types of mutation.\textsuperscript{133,135} Approximately 30\% of patients
with Ellis-van Creveld syndrome have no mutations in either of these genes, suggesting that greater genetic heterogeneity may be present.\textsuperscript{136} The syndrome is characterized by bone abnormalities, nail dysplasia, orofacial abnormalities, and cardiovascular malformations.\textsuperscript{137} Patients have a short stature, acromesomelic limb shortening (more prominent in the distal region), and a narrow chest. Polydactyly, syndactyly, genus valgum, and various types of tooth abnormalities are common.\textsuperscript{137,138}

**Weyers Acrodental Dysostosis**

Weyers acrodental dysostosis is an autosomal dominant disorder whose causative mutations are located in the EVC and EVC2 genes.\textsuperscript{133,134,137} The transmission pattern and milder phenotype distinguish this condition from Ellis-van Creveld syndrome.\textsuperscript{133} Clinical expression is variable and characterized by short stature, hypotelorism, prominent ears, postaxial polydactyly, oral abnormalities (irregular, small, peg-shaped teeth and hypodontia), and onychodystrophy (dysplastic or hypoplastic nails).\textsuperscript{133,137}

**Group 2**

**Hidrotic Ectodermal Dysplasia**

Hidrotic ectodermal dysplasia, also known as Clouston syndrome, is caused by mutations in the GJB6 gene which is located on chromosome 13 (locus 13q11-q12.1) and which encodes connexin 30.\textsuperscript{139} This autosomal dominant disorder is particularly common among French-Canadian individuals,\textsuperscript{140} and only appears very exceptionally de novo.\textsuperscript{141} Mutations in this gene can also give rise to other disorders such as autosomal dominant and autosomal recessive sensorineural deafness.\textsuperscript{142}

Connexins are transmembrane proteins that facilitate intercellular communication.\textsuperscript{140} Connexin molecules form hexamers called connexons, which interact with other connexons of adjacent cells to form intercellular gap junctions.\textsuperscript{142} These channels allow the diffusion of small molecules between cells and mediate signal and nutrient exchange, thereby coordinating cell activities and response to stimuli. More than 10 different connexons have been identified in skin. Each connexon seems to have its own specific properties, and mutations are responsible for a distinct skin disorder. Thus, hidrotic ectodermal dysplasia and KID syndrome\textsuperscript{140} are caused by mutations in the GJB6 and GBJ2 genes, which encode connexin 30 and connexin 26, respectively.\textsuperscript{142} These 2 connexons share 76\% of their amino acid sequence and are coexpressed in the stratum corneum, sweat glands, and hair follicles.\textsuperscript{140} This overlap, despite the different tissue expression of connexin 26 and connexin 30, implies that certain functions are shared and that there is perhaps a direct interaction between the 2 proteins in many ectodermal epithelia. In fact, both are associated with certain clinical characteristics such as nail dystrophy, hair loss, and plantar keratoderma, and recently there has been a report of a patient with a connexin 30 mutation whose clinical manifestations were similar to those of keratitischthyosis-deafness (KID) syndrome.\textsuperscript{140}

The 3 main clinical characteristics of hidrotic ectodermal dysplasia are hair loss, nail dystrophy, and palmoplantar keratoderma (Figs. 15 and 16).\textsuperscript{140} Unlike patients with HED, patients with hidrotic ectodermal dysplasia have normal teeth and sweat and sebaceous gland function.\textsuperscript{140,143} Hair abnormalities are manifest as atrichia or hypotrichosis, which may progressively worsen;\textsuperscript{140} the fine, slow-growing hair has a disorganized structure and reduced birefringence.\textsuperscript{144} Women are completely bald, whereas men show expression that varies from fair hair with focal alopecia to complete baldness.\textsuperscript{145} The eyebrows and eyelashes are scant or absent, as is pubic and axillary hair.\textsuperscript{140} Nail disorders range from an almost normal appearance to micronychia or anonychia; the nail plate may show thickening, desquamation, color changes, striation, and onycholysis.\textsuperscript{140} Nail abnormalities in these patients may be reminiscent
of congenital pachyonychia. Some patients also present diffuse palmpoplantar keratoderma and discrete skin hyperpigmentation, which is particularly evident underneath the free edge of the nails and on the finger and toe joints, knees, and elbows. Eccrine syringofibroadenomas have been reported in several patients and there has also been an isolated case of congenital pseudoainhum. These clinical manifestations may be accompanied by strabism, conjunctivitis, pterygium, cataracts, sensorineural deafness, polydactyly, and syndactyly, but facial dysmorphism is not present and general physical development is normal.

Zlotogora-Ogur Syndrome or Ectodermal Dysplasia With Cleft Palate

The autosomal recessive disorder Zlotogora-Ogur syndrome is caused by mutations in the poliovirus receptor-like 1 (PVRL1) gene, located on chromosome 11 (locus 11q23.2), which encodes the nectin-1 protein. Nectins are calcium-independent cell-cell adhesion molecules that act at cell-cell junctions sometimes in conjunction with cadherins. So far, 4 different types of nectins have been reported. Nectin-1 is expressed in several ectodermal tissues, including the skin, teeth, and hair, as well as some areas, particularly in the lateral regions. Xerosis, hypoplastic dermatoglyphs, and progressive palmpoplantar hyperkeratosis are also observed. Tooth abnormalities include delay in dental eruption, microdontia, hypodontia, and anodontia. Nails are normal or mildly dystrophic. Patients have peculiar facial features, with an oval face and large antverted ears. Syndactyly, which may be partial, is often present in the second, third, and fourth fingers, and can sometimes affect both hands. Other manifestations include deafness, genitourinary or renal abnormalities, nipple abnormalities, and lumbar lordosis, and variable mental retardation. Differential diagnosis should be established mainly with EEC syndrome, with which it shares most manifestations. The main difference is in the transmission pattern (EEC syndrome follows autosomal dominant inheritance) and limb malformations, mainly ectrodactyly, which are present in 85% of the patients with EEC syndrome.

In August 2010, a second nectin-derived condition was reported arising from an abnormality in nectin 4, which is encoded by PVRL4. This syndrome is similar to the one described above, but there is no cleft palate and it is known as ectodermal dysplasia-syndactyly syndrome.

Ectodermal Dysplasia-Fragile Skin Syndrome

Ectodermal dysplasia-fragile skin syndrome is an autosomal recessive condition that was recently reclassified as an epidermolysis bullosa simplex. It is caused by mutation in the plakophilin gene (PKP1), located on chromosome 1 (locus 1q32). PKP1 is a structural component of desmosomes and is expressed in the stratified squamous epithelium, the myocardium, the meninges, and part of the lymph nodes. Like other types of epidermolysis bullosa, the condition is characterized by substantial trauma-induced skin fragility, generalized erythema, alopecia, nail dystrophy, and focal keratoderma with painful fissures (Fig. 17). Some patients present hypohidrosis, but the teeth are normal in all cases. Histologic study shows widened intercellular spaces, separation of keratinocytes, intraepidermal clefts, acantholytic keratinocytes, and different degrees of dyskeratosis, but to date the development of skin carcinomas has not been reported.

Ectodermal Dysplasia-Ectrodactyly-Macular Dystrophy Syndrome

Ectodermal dysplasia-ectrodactyly-macular dystrophy (EEM) syndrome is an autosomal recessive disorder caused by a mutation in the CDH3 gene, located on chromosome 16 (locus 16q22.1); this gene encodes the cadherin-3 protein. Cadherins are calcium-dependent adhesion molecules with several extracellular domains, a transmembrane region, and an intracellular region. The intracellular region binds to β-catenin, which is implicated in transcription and cellular adhesion. Expression of CDH3 during embryogenesis is important for normal development. It is expressed at least in the orofacial region and pharyngeal arches, as well as in the limbs, and it may play an important role in the morphology of the human hand. EEM syndrome is characterized by syndactyly, retinal degeneration, and sparse hair, although the clinical manifestations
are variable. In addition to syndactyly, which may be bilateral, 1 or several phalanges may be missing or fingers or toes may be completely hypoplastic. The hands are usually more severely affected than the feet. Another key sign is progressive retinal degeneration, with gradual vision loss. Prominent pigmentation is observed in the posterior pole of the retina, along with macular atrophy. Patients may also have hypotrichosis with sparsely populated eyebrows, few eyelashes, and tooth abnormalities (hypodontia and small and very separated teeth).

Odonto-Onycho-Dermal Dysplasia

The autosomal recessive disorder, odonto-onycho-dermal dysplasia, is due to mutations in the WNT10A gene, located on chromosome 2 (locus 2q35). The WNT genes encode a large family of glycoproteins implicated in a signaling pathway crucial for the development of ectodermal-derived tissue during embryogenesis and adult life. Thus, WNT10A is important for tooth and hair follicle formation, and for epidermal regeneration, lingual papillae formation, and sweat gland function. Although the condition is termed odonto-onycho-dermal dysplasia, tricho-onycho-dermal dysplasia would be more appropriate given the hair involvement. Characteristic skin lesions include the appearance in the facial region of reticular, erythematous, telangiectatic, atrophic plaques, which become more intense with heat. Another frequent observation is palmoplantar hyperkeratosis, accompanied by hyperhidrosis and painful fissuring. Other abnormalities include the presence of smooth tongue with reduced or absent papillae, pilaris keratosis, hypotrichosis, and tooth and nail abnormalities. Some patients may be slightly mentally retarded. Different mutations in this same gene are responsible for another autosomal recessive ectodermal dysplasia, Schopf-Schulz-Passarge syndrome. This syndrome shares certain clinical features (hypodontia, nail dystrophy, palmoplantar keratoderma, smooth tongue, hyperhidrosis, and hypotrichosis), but in addition, patients have other features such as cysts in the eyelids and an increased risk of developing skin tumors.

In conclusion, ectodermal dysplasias are a heterogeneous group of hereditary disorders that bear many similarities and are difficult to classify. Biomolecular findings in recent years have brought us closer to a useful clinical-functional classification in clinical practice given that different genetic abnormalities in different functional pathways can be linked to a given phenotype. However, many disorders within the group of ectodermal dysplasias have yet to be studied or identified. Nevertheless, the dermatologist should be aware of the main signs and symptoms of these disorders when searching for a diagnosis. In addition, carriers should be identified so that genetic counseling can be offered.
