Severe visual field alterations in patients with optic nerve drusen

Alteraciones campimétricas graves en pacientes con drusas de nervio óptico

Dear Editor:

Optic nerve drusen (OND) are globular hyaline bodies measuring 5 to 1000 μm in diameter and located anterior to the lamina cribrosa. They contain amino acids, nucleic acids, iron, and calcium, and have a clinical incidence of 3.4 per 1000 adults; histological autopsy studies reflect higher incidence. Pathogenesis is not well understood, but the most widely accepted theories suggest an alteration in the axoplasmic transport of ganglion cells. They tend to be bilateral, asymmetrical, and more common in females; drusen formation is a dynamic process that generally begins in the second decade of life. Most cases are idiopathic in origin, although some show autosomal dominant transmission. Drusen are associated with such ocular vascular anomalies as cilioretinal arteries, pronounced vessel tortuosity, abnormal bifurcations, collateral retinochoroidal vessels, peripapillary neovascularisation, and occlusive vascular diseases.

One type of OND is known as hidden or deep, with elevated papillae and poorly-defined edges; ultrasound images of this type do not reveal a nodular appearance. Visible or superficial OND, in turn, appear as yellowish nodules of different numbers and sizes within a papilla that is typically elevated and displays poorly-defined edges.

We present a clinical case of OND with severe visual field alterations and marked atrophy of the retinal nerve fibre layer (RNFL).

Our patient was a 40-year-old man referred by the neuro-ophthalmology unit for an evaluation of pseudopapilloedema. The patient was asymptomatic and had no relevant personal or family history.

Visual acuity was 0.60 in both eyes (OU); intraocular pressure (IOP) was 14mmHg in OU. Biomicroscopy results were normal, and the fundus displayed elevated and asymmetrical papillae with round, yellowish deposits (Fig. 1).

Visual field analysis, performed using Octopus 1-2-3® and the G1X program, detected a bilateral nasal arcuate defect (Fig. 2A). Optic nerve tomography (ONT) showed a decrease in the nerve fibre layer in the temporal, superior, and inferior regions of OU (Fig. 2B).

OND may result in loss of central visual acuity, although this is infrequent. They can also cause severe visual field deficits, some of which may mimic those seen in glaucoma.

These deficits, added to the difficulty of examining the optic disc when OND are present, complicate diagnosis and follow-up in patients with possible glaucomatosus lesions.

B-mode ultrasonography is the most reliable means of diagnosing OND. They may also be detected using

Figure 1  Fundus showing raised, asymmetrical papillae with round yellowish deposits.

flourescein angiography (fundus autofluorescence), CT, and
fundoscopy.5

The most frequently identified visual field changes are
arcuate defects, generalised visual field constriction, and
enlarged blind spot; all types are slowly progressive. The
visual field defect may or may not correspond to the OND
location.4

The pathophysiological mechanisms that give rise to
functional changes are as follows: impaired axonal transport
in an eye with a small scleral canal, gradual secondary
wear on optic nerve fibres, direct compression of drusen on
prelaminar nerve fibres, and ischaemia in the optic nerve
head.4

Visual acuity may decrease in some cases due to asso-
ciated complications, including haemorrhages, arterial and
venous occlusion, neovascular membranes, etc.; associated
disease, such as retinitis pigmentosa or angioid streaks; and
other concomitant causes, whether unrelated to the drusen
or caused exclusively by drusen.2

Decreased visual acuity associated with papillary drusen
is uncommon. When this defect is present, it is usually mod-
erate and almost always associated with peripheral field
changes. Visual acuity is significantly linked to the presence
and number of visible drusen. Loss of central visual acuity
without a visual field defect should orient us towards other
associated causes.3

Experts recommend using B-mode ultrasonography to
confirm the presence of OND and monitoring patients with
visual field analysis and ONT to check the level of impair-
ment of the nerve fibre layer.6

ONT and scanning laser polarimetry (GDx) have shown
thinning of the nerve fibre layer in patients with OND, with
greater losses being associated with more numerous and
visible drusen. ONT seems to be the more sensitive than
perimetry for detecting nerve fibre loss in its early stages.7

There is no consensus regarding treatment. Some studies
have shown radial neurotomy to be effective since it relieves
the pressure that drusen exert on nerve fibres. Others rec-
ommend neuroprotective agents, but not enough studies
have been carried out to demonstrate the efficacy of this
procedure.8

In conclusion, although OND are asymptomatic, the visual
field defects they cause can be severe. We recommend using

visual field analysis and ONT to monitor the status of these
patients, and if their findings indicate progression, consider
treatment with neuroprotective agents.
