Introduction

The identification of conditions predisposing a patient to thrombosis is essential for the prevention and treatment of acute myocardial infarction, stroke, pulmonary embolism, and venous thrombosis. Accordingly, this knowledge should reduce the morbidity and mortality rates of patients with venous or arterial thrombosis.

Hyperhomocysteinemia is associated with an increased risk of arterial thrombosis (e.g. myocardial infarction, stroke, peripheral vascular disease) and may be associated with a higher risk of venous thrombosis. Therefore, clinical conditions normally associated with hyperhomocysteinemia, such as folic acid and vitamin B12 deficiencies, may also be associated with a higher risk of thrombosis.

The present report presents an unusual case of multiple and simultaneous venous thromboses in a patient with hyperhomocysteinemia secondary to pernicious anemia-induced vitamin B12 deficiency, who was treated with short-term anticoagulation therapy and vitamin B12 and folic acid supplementation.

Case report

A 58-year-old man was admitted to the emergency room owing to acute pain in the right hemiabdomen lasting three days. No fever, jaundice, or respiratory, urinary, or gastrointestinal changes had occurred. The patient's comorbidities included Chagas disease (indeterminate chronic phase) and systemic arterial hypertension (regular losartan use). He had no history of tobacco or alcohol use, recent surgery, or prolonged immobilization (including long trips). A physical examination at the time of admission revealed normal findings, with no signs of peritoneal irritation.

Laboratory tests revealed discreet normocytic-normochromic anemia [hemoglobin (Hb): 12.0 g/L; mean corpuscular volume (MCV): 98.1 fl; and mean corpuscular hemoglobin: 33.1 pg] and increased serum lactate.
The association between hyperhomocysteinemia and pernicious anemia is an autoimmune condition that may co-occur with a loss of vitamin B12 deficiency. Several mechanisms have been proposed to link hyperhomocysteinemia with endothelial damage/dysfunction and consequently an increased risk of thrombosis, including decreased levels of nitric oxide, asymmetric dimethylarginine catabolism reduction, vascular smooth muscle proliferation, and platelet activation via increased thromboxane A2 biosynthesis, leukocyte activation, and disruption of the hemostatic balance between coagulant and fibrinolytic mechanisms.

Dietary restriction, nitric oxide abuse, malabsorption states (e.g., pernicious anemia, celiac disease, *Helicobacter pylori* infection) and adverse effects of various drugs (e.g., metformin, omeprazole, oral contraceptives) are known causes of vitamin B12 deficiency. Pernicious anemia is an autoimmune condition that may co-occur with a loss of vitamin B12 deficiency and consequent increase in the homocysteine serum levels. Accordingly, patients with pernicious anemia would be expected to have a higher incidence of thrombosis. The present case is peculiar because it

Venous thromboembolism (VTE) is an important cause of intra- and extra-hospital morbidity and mortality. Thus, it is essential to identify the factors associated with an increased thrombotic risk during the establishment of measures to prevent and treat thromboses.

Hyperhomocysteinemia, although a risk factor for thrombosis, is more consistently associated with arterial events such as stroke, myocardial infarction and peripheral vascular disease. The association between hyperhomocysteinemia and venous thrombosis remains highly controversial. Previous studies have reported two- to three-fold higher risks of VTE among patients with hyperhomocysteinemia. Furthermore, a meta-analysis of 24 retrospective and three prospective epidemiological studies reported a modest, although real, association between hyperhomocysteinemia and VTE (27% increase in risk in the prospective studies, and 60% increase in retrospective studies for every 5-μmol/L increase in serum homocysteine levels). Moreover, an increased incidence of venous thrombosis has been observed among Brazilian patients with hyperhomocysteinemia.

Hyperhomocysteinemia is the result of defective renal homocysteine excretion or deficiencies in enzymes or cofactors associated with pathways that convert homocysteine to methionine or cysteine via remethylation or transsulfuration, respectively. Several mechanisms have been proposed to link hyperhomocysteinemia with endothelial damage/dysfunction and consequently an increased risk of thrombosis, including decreased levels of nitric oxide, asymmetric dimethylarginine catabolism reduction, vascular smooth muscle proliferation, platelet activation via increased thromboxane A2 biosynthesis, leukocyte activation, and disruption of the hemostatic balance between coagulant and fibrinolytic systems.

The treatment of this patient comprised parenteral vitamin B12 replacement (associated with vitamin B6 and thiamine) and oral folic acid replacement (5 mg/day). Vitamin replacement therapy was maintained regularly even after the anemia was corrected (Hb: 16.2 g/L; MCV: 80.1 fl). During outpatient follow-up, the patient continued to receive anticoagulation therapy for ten months. The oral anticoagulation was suspended after his serum vitamin B12 level had normalized (579 ng/dL) and his serum homocysteine level had decreased (19.2 μmol/L). No thrombotic recurrences were detected in a 26-month follow-up evaluation.

The patient’s monozygotic twin brother was invited to undergo clinical and laboratory evaluations, during which a vitamin B12 deficiency, mildly elevated homocysteine levels (20 μmol/L) and seroreactivity to anti-parietal cell antibodies were detected. Despite the absence of cytopenia or a history of thrombosis, folic acid, vitamin B6 and vitamin B12 treatment was initiated for the patient’s twin.

### Discussion

Venous thromboembolism (VTE) is an important cause of intra- and extra-hospital morbidity and mortality. Thus, it is essential to identify the factors associated with an increased thrombotic risk during the establishment of measures to prevent and treat thromboses.

Hyperhomocysteinemia, although a risk factor for thrombosis, is more consistently associated with arterial events such as stroke, myocardial infarction and peripheral vascular disease. The association between hyperhomocysteinemia and venous thrombosis remains highly controversial. Previous studies have reported two- to three-fold higher risks of VTE among patients with hyperhomocysteinemia. Furthermore, a meta-analysis of 24 retrospective and three prospective epidemiological studies reported a modest, although real, association between hyperhomocysteinemia and VTE (27% increase in risk in the prospective studies, and 60% increase in retrospective studies for every 5-μmol/L increase in serum homocysteine levels). Moreover, an increased incidence of venous thrombosis has been observed among Brazilian patients with hyperhomocysteinemia.

Hyperhomocysteinemia is the result of defective renal homocysteine excretion or deficiencies in enzymes or cofactors associated with pathways that convert homocysteine to methionine or cysteine via remethylation or transsulfuration, respectively. Several mechanisms have been proposed to link hyperhomocysteinemia with endothelial damage/dysfunction and consequently an increased risk of thrombosis, including decreased levels of nitric oxide, asymmetric dimethylarginine catabolism reduction, vascular smooth muscle proliferation, platelet activation via increased thromboxane A2 biosynthesis, leukocyte activation, and disruption of the hemostatic balance between coagulant and fibrinolytic systems.

Dietary restriction, nitric oxide abuse, malabsorption states (e.g., pernicious anemia, celiac disease, *Helicobacter pylori* infection) and adverse effects of various drugs (e.g., metformin, omeprazole, oral contraceptives) are known causes of vitamin B12 deficiency. Pernicious anemia is an autoimmune condition that may co-occur with a loss of vitamin B12 deficiency and consequent increase in the homocysteine serum levels. Accordingly, patients with pernicious anemia would be expected to have a higher incidence of thrombosis.
involves a patient with multiple simultaneous thromboses (including the abdominal vein) and a moderately elevated serum homocysteine level caused by a pernicious anemia-induced vitamin B12 deficiency. Few previous articles have reported an association between pernicious anemia and thrombosis, although some authors have reported recurrent or unusual vascular bed thrombosis in patients with vitamin B12 deficiency.

Currently, no treatment has been established for hyperhomocysteinemia. Although folic acid and vitamin B6 and/or vitamin B12 supplementation can reduce serum homocysteine levels, this does not necessarily confer a reduced risk of thrombosis. Accordingly, this failure to mitigate risk raises questions regarding the actual benefits of vitamin supplementation and the potential participation of unidentified thrombosis mediators independently of homocysteine levels. However, some authors have speculated about the benefits from such treatment. Weiss et al. suggested that folic acid supplementation reduces the risk of thrombosis by promoting nitric oxide biosynthesis independently of the homocysteine level. In this case, no recurrence of thrombosis was observed during vitamin B12 and folic acid supplementation.

In conclusion, studies of the intrinsic relationship between homocysteine, vitamin B12 and venous thrombosis remain necessary. In particular, studies of hyperhomocysteinemia in patients with unexplained venous thrombosis should be conducted systematically, with the intent to identify the etiology and provide prophylactic interventions for secondary VTE. Finally, the absence of anemia and macrocytosis as signs of vitamin B12 or of folic acid deficiency should not discourage studies on hyperhomocysteinemia.
