ARTICLE INFO

ABSTRACT

We used 16S rRNA sequencing to assess the archaeal communities across a gradient of Cerrado. The archaeal communities differed across the gradient. Crenarchaeota was the most abundant phyla, with Nitrospirae and NRPJ as the predominant classes. Euryarchaeota was also found across the Cerrado gradient, including the classes Metanocellales and Methanomassiliicocaceae.

Soil microorganisms constitute a third of the Earth’s biomass, playing important ecological and biogeochemical roles in terrestrial ecology. Among the microorganisms that inhabit soils, the domain Archaea is particularly important because it is abundant and plays important roles in C and N cycling. This domain constitutes one of the three major evolutionary lineages of life on Earth, and although it has long been believed that these organisms mainly inhabit extreme environments, previous studies demonstrated that they are widely distributed around the world in different types of soils.

Since the recognition of the archaean domain in the tree of life, studies have been focused to explore their presence and function in a wide range of environments. With the advance of DNA-based molecular tools and genomic analysis, the knowledge of this domain has evolved and the...
current archael classification is rapidly moving. Presently, 20 archael phyla are recognized by small subunit RNA databases; however, it has been reported that 14 phyla have no cultured representative. Most of culturable members of Archael belong to the two main phyla Euryarchaeota and Crenarchaeota. Other new phyla have been proposed in the last years, for example Nanoarchaeota, based on the isolation of a hyperthermophilic symbiont Nanoarchaeum equitans and Thaumarchaeota. Most recently, two superphylum have been proposed, namely (i) TACK, which includes the phyla Thaumarchaeota, Aigarchaeota, Crenarchaeota and Korarchaeota, and (ii) Asgard, which consist in a sister group to TACK and are considered more closely related to the original eukaryote. Together with the advance of Archael classification, their functional role in the ecosystem has also been the focus of recent studies. Members of Archael carry out many steps in the nitrogen cycle, such as nitrate-based respiration and denitrification. Communities of autotrophic and heterotrophic Archael catalyze iron and sulfur oxidation, which influence the release rate of metals and sulfur to the environment. Also, according to the carbon cycle, all known methanogen organisms belong exclusively to Archael domain and are generally found in oxygen-depleted environments.

In Brazil, studies regarding the diversity of Archael have been conducted for some important ecosystems, such as Amazonian and Atlantic forests, as well as in mangroves. In the case of the Brazillian Cerrado, previous studies investigated the diversity of archael in soils from the Central Plateau and found that Crenarchaeota was the most abundant archael group in the ecosystem. However, it has been hypothesized that the vegetation and soil conditions in the Cerrado from Northeastern Brazil differs from those of the Central Plateau. Therefore, the pattern of Archael communities would be different because the vegetation and soil conditions drive soil microorganisms. Previous studies have shown differences between bacterial diversity in the soils obtained from Cerrado in the Northeast when compared to those from the Central Plateau. Therefore, we used next-generation sequencing of the 16S rRNA gene in soil samples from vegetation gradients obtained from Campo gramineoide, Cerrado stricto sensu, Cerrado and Floresta decidual to understand the diversity of Archael in the soils of Cerrado in Northeastern Brazil.

The study was conducted in a preserved Brazilian Cerrado within Sete Ciades National Park (PNSC) (04°02’-08’S and 41°40’-45’W), Northeast, Brazil. This region presents two distinct seasons (wet and dry) with an annual average temperature at 25 °C and rainfall of 1558 mm distributed in February through April. We evaluated four different areas (with 1000 m² each one) in a gradient of vegetation (‘Campo gramineoide’, ‘Cerrado stricto sensu’, ‘Cerrado’ and ‘Floresta decidual’) (Table 1, Fig. 1).

Each area was separated in three transects (replication) where soil samples were collected at top soil layer (0–20 cm depth; three points per transect) in March (wet season), 2014. All soil samples were immediately stored in sealed plastic bags and transported in an icebox to the laboratory. A portion of the soil samples was stored in bags and kept at −20 °C for DNA analysis and another portion was air-dried, sieved through a 2-mm screen and homogenized for chemical analyses using standard laboratory protocols.

Soil DNA was extracted from 0.5 g (total humid weight) of soil using the PowerLyzer PowerSoil DNA Isolation Kit (MoBio Laboratories, Carlsbad, CA, USA), according to the manufacturer’s instructions. The quality of the extracted DNA was checked with the Nanodrop ND-1000 spectrophotometer (Thermo Scientific, Waltham, MA, USA), and it was quantified by Quibit® 2.0 fluorometer using the dsDNA BR Assay kit (Invitrogen®). The integrity of the DNA was also confirmed by electrophoresis in a 0.8% agarose gel with 1× TAE buffer. The ampiclon library of the archael 16S rRNA genes were amplified using the region-specific primers (S15F/806R). The first step amplification comprised 25 μL reaction containing the following: 14.8 μL of nuclease-free water (Certified Nuclease-free, Promega, Madison, WI, USA), 2.5 μL of 10× High Fidelity PCR Buffer (Invitrogen, Carlsbad, CA, USA), 1.0 μL of 50 mM MgSO₄, 0.5 μL of each primer (10 μM concentration, 200 pM final concentration), 1.0 unit of Platinum Taq polymerase High Fidelity (Invitrogen, Carlsbad, CA, USA), and 4.0 μL of template DNA (10 ng). The conditions for PCR were as follows: 94 °C for 4 min to denature the DNA, with 35 cycles at 94 °C for 45 s, 50 °C for 60 s, and 72 °C for 2 min, with a final extension of 10 min.

at 72 °C. In the second step, a unique pair of Illumina Nextera XT indexes (Illumina, San Diego, CA) was added to both ends of the amplified products. Each 50 µL reaction contained the following: 23.5 µL of nuclease-free water (Certified Nuclease-free, Promega, Madison, WI, USA), 5.0 µL of 10× High Fidelity PCR Buffer (Invitrogen, Carlsbad, CA, USA), 4.8 µL of 25 mM MgSO4, 1.5 µL of dNTP (10 mM each), 5.0 µL of each Nextera XT index (Illumina, San Diego, CA, USA), 1.0 unit of Platinum Taq polymerase High Fidelity (Invitrogen, Carlsbad, CA, USA), and 5.0 µL of each product from previous PCR. The conditions for this second round PCR were as follows: 95 °C for 3 min to denature the DNA, with 8 cycles at 95 °C for 30 s, 55 °C for 30 s, and 72 °C for 30 min, with a final extension of 5 min at 72 °C.

After indexing, the PCR products were cleaned up using Agencourt AMPure XP – PCR purification beads (Beckman Coulter, Brea, CA, USA), according to the manufacturer’s manual, and quantified using the dsDNA BR assay Kit (Invitrogen, Carlsbad, CA, USA) on a Qubit 2.0 fluorometer (Invitrogen, Carlsbad, CA, USA). Once quantified, different volumes of each library were pooled into a single tube in equimolar concentration. After quantification, the molarity of the pool was determined and diluted to 2 nM, denatured, and then diluted to a final concentration of 8.0 pM with a 20% PhiX (Illumina, San Diego, CA, USA) spike for loading into the Illumina MiSeq sequencing machine (Illumina, San Diego, CA, USA).

Sequence data were processed using QIIME following the UPARSE standard pipeline according to Brazilian Microbiome Project22 to produce an OTU table and a set of representative sequences. Briefly, the reads were truncated at 240 bp and quality-filtered using a maximum expected error value of 0.5. Pre-filtered reads were dereplicated and singletons were removed and filtered for additional chimeras using the RDP gold database using USEARCH 7.0. These sequences were clustered into OTUs at a 97% similarity cutoff following the UPARSE pipeline. After clustering, the sequences were aligned and taxonomically classified against the Greengenes database (version 13.8).23 The sequences were submitted to the NCBI Sequence Read Archive under the number SRP091586.

Redundancy Analysis (RDA) was used to determine the correlation between archaeal community structure and soil physicochemical properties. The OTU table was initially analyzed using Detrended Correspondence Analysis (DCA) to evaluate the gradient size of the species distribution, which indicated linearly distributed data (length of gradient <3),
revealing that the best-fit model for the data was RDA. Forward selection (FS) and the Monte Carlo permutation test were applied with 1000 random permutations to verify the significance of soil chemical properties upon a microbial community. We used permutational multivariate analysis of variance (PERMANOVA)23 to test whether sample categories harbored significantly different archael community structure. RDA plots were generated using the software Canoco 4.5 (Biometrics, Wageningen, The Netherlands), and PERMANOVA and alpha diversity index were calculated with the software PAST.25 To determine the differences in abundance of archael groups among soil samples, the Statistical Analysis of Metagenomic Profiles (STAMP) software package was used.26 The OTU table was used as input, and P-values were calculated using the two-sided Welch’s t-test,27 while confidence intervals were calculated using DP Welch’s inverted and correction was made using Benjamini–Hochberg false discovery rate.28

In this study, we examined the archael structure and composition in the soils from vegetation gradients from the Cerrado. We used 16S rRNA sequencing to assess the archael communities and correlated them with soil chemical parameters. Our results showed that soil parameters differed between the sampling sites. Areas under Campo graminioide, Cerrado stricto sensu and Cerrado presented the highest soil temperature and the lowest N, P, K, and CEC compared with Floresta decidual (Table 2). Soil moisture, pH, and TOC content were similar between Cerrado stricto sensu and Cerrado, and they were the lowest and highest in Campo graminioide and Floresta decidual, respectively.

These markedly different soil conditions, mainly between Campo graminioide and Floresta decidual, exist because of the differences in plant cover and the communities, both of which can influence soil properties. For example, Campo graminioide is covered mostly by grasses, whereas Floresta decidual is covered by trees. RDA showed the differences between the archael communities across the gradients (Fig. 2) and indicated that the Floresta decidual was the most distinct compared to the other areas.

Additionally, RDA showed that the composition of archael communities was strongly correlated with specific soil properties across the Cerrado gradients. Our results showed that the archael community of Floresta decidual correlated with soil moisture, TOC, CEC, P, K, and N. On the other hand, soil temperature and pH correlated with Campo graminioide, Cerrado stricto sensu and Cerrado. These results indicate that the archael community differs across the gradients of the Cerrado and is influenced by soil conditions. Because Campo graminioide, Cerrado stricto sensu and Cerrado had similar soil conditions, their archael communities were more similar to each other when compared to Floresta decidual. According to Catão et al.,3 the soil conditions drive the differences in the diversity of Archael in the Brazilian Cerrado. These authors compared and contrasted Cerrado denso and Mata de Galeria from the Brazilian Cerrado and found differences in the community structures of Archael. The varied soil conditions found across the gradients of vegetation have influenced the bacterial diversity.15 Interestingly, our results highlight the soil pH as a significant driver of archael communities in these soils. According to Gorres,29 soil pH is the main driver of archael community structure in soils. This strong correlation between soil pH and the microbial community structure may be because pH and the other physicochemical soil parameters are so closely related. Most microorganisms have intracellular pH that varies in the range of pH 7 ± 1; therefore, a small variation of the environmental pH could expose microorganisms to stress. Archael were detected in all analyzed samples and showed very low diversity compared to the bacterial community found in the same samples.18 Interestingly, Floresta decidual presented the lowest alpha diversity when compared to the other areas (Fig. 3). It has been suggested that an environment in equilibrium, such as forest, the ecosystem functioning is maintained based on lower levels of diversity, but high abundance of microorganisms; in contrast, environments under stress would present an increased diversity, which leads to a higher functional diversity and, consequently,

the maintenance of essential ecosystem functions.30 Considering that Cerrado areas are more prone to environmental stress, such as high temperature, low moisture and oligotrophy, the higher archaeal diversity would be expected. A total of 3078 reads were clustered in 33 OTUs according to the Greengenes taxonomical classification. We found Crenarchaeota to be the most abundant phyla across the Cerrado gradients, among which Nitrospira and NRPJ were the predominant classes (Fig. 4). Organisms belonging to the largely non-thermophilic Crenarchaeota appear to be ubiquitous in soil systems and are dominant over euryarchaeal populations in grassland soils.31 These findings agree with previous studies in the Brazilian Cerrado, which have reported Crenarchaeota as most dominant phylum and Nitrospira as an important group.3,16 The relative abundance of Nitrospira and NRPJ differed across the regions. Floresta decidual showed the highest abundance of Nitrospira, whereas Campo graminoides, Cerrado stricto sensu and Cerrado showed the highest abundance of NRPJ. Previously, Nicol et al.32 have indicated that Crenarchaeota from soils may have specific association with plant roots, playing an important role in the rhizosphere. Nitrospira are important ammonia-oxidizer organisms,33 and although ammonia oxidation occurs in both Bacteria and Archaea, the archaeal group dominates in both soil and marine environments.34 Nitrogen-related microorganisms are commonly found abundantly in forest soils,30 which may explain the higher abundance of Nitrospira in our forest samples. Also, Navarrete et al.35 showed that the diversity of ammonia-oxidizing archaeal communities tend to be higher in primary forests. On the other hand, the NRPJ group was more abundant in Cerrado sites. This group belongs to the Marine Benthic Group A, an uncultured archaeal cluster initially described from cold continental slope and deep-sea sediments.36 Members of this group are commonly found in oligotrophic soils, such as boreal forests,37 which may explain its higher abundance in our Cerrado samples. In summary, our results showed a high abundance of Crenarchaeota groups in our samples, with differential abundance between sites, suggesting that members of this group play distinct and important roles in the soil ecosystem.

The phylum Euryarchaeota is considered the most physiologically diverse and includes methanogens, halophiles and thermophile organisms. Members of this phylum were also found across the Cerrado gradients, including the classes Methanococcales and Methanomassiliicoccales. Interestingly, the Methanococcales class was detected only at Campo graminoides, which also had a high abundance of Methanomassiliicoccales. Similarly, Cerrado stricto sensu showed high abundance of Methanomassiliicoccales. The family Methanomassiliicoccales comprises of a methanogenic lineage of the class Thermoplasmata, and members of the Methanococcales family are methanogenic organisms, contributing to the global methane cycle.38 In this sense, our results show that important groups related to carbon cycle are abundant in Campo graminoides and Cerrado stricto sensu.

As shown in the RDA, pH was the main driver of the archaea communities across the gradients. It has been described that pH dominates the variation of archaeal diversity and community composition in tropical soils. In a large-scale study, the authors showed a niche specialization of terrestrial archaeal ammonia oxidizers based on pH, showing that amoA abundance and diversity increased with soil pH. In our samples, the high soil pH found in the Floresta decidual area favored the dominance of Nitrospiraerales, which is sensitive to low pH. On the other hand, a high abundance of Euryarchaeota, specifically Metanocellales, in the Campo gnaminoide region may be related to the low soil pH found in this area. According to Hu et al., soil pH is a driver of methanogenesis and subsequently may promote shifts in the archaeal community composition from Crenarchaeota to methanogenic Euryarchaeota.

In conclusion, our data showed that although the most of detected taxa are shared between all four areas, the archaeal structure and abundance differed across these gradients and was strongly driven by soil physicochemical properties. The soil pH was the main driver of archaeal communities in the studied soils, and this can be explained by the difference between the sites, where Floresta decidual presented higher values while Campo gnaminoide was more acid. Results showed that Crenarchaeota was the most dominant phylum, followed by Euryarchaeota. Additionally, diﬀerential soil parameters lead to distinct functional potential of the communities, where Floresta decidual presented high abundance of groups related to the nitrogen metabolism while Campo gnaminoide and Cerrado stricto sensu presented high abundance of groups related to carbon metabolism. Also, Nitrospiraerales was the most abundant order found across the gradients, and further studies are needed to evaluate their potential in N cycling.
