We describe 3 patients with ventricular tachycardia in whom epicardial ablation was done after prior attempts of endocardial ablation had failed. Clinical ventricular tachycardia originated at the right ventricular outflow tract in 1 patient and near the mitral annulus in another patient. In these 2 cases ventricular tachycardia was mapped and successfully ablated with a percutaneous subxiphoid approach to the pericardial space. In the remaining patient, ventricular tachycardia originated near the mitral annulus and was ablated via a coronary vein. The 2 patients who presented tachycardiomyopathy recovered normal left ventricular function after successful ablation. Failure of endocardial ablation may reflect a substrate of epicardial arrhythmia. Epicardial ablation is effective and provides an alternative therapy for patients with ventricular tachycardia, including those with no structural heart disease.

Key words: Catheter ablation. Radiofrequency. Arrhythmia.

INTRODUCTION

Percutaneous, epicardial, radiofrequency ablation is a non-surgical technique for treating ventricular tachycardia (VT). Its use has been described in patients with VT caused by Chagas disease and prior myocardial infarction, although rarely in patients with VT but with no structural heart disease.1-11

PATIENTS AND METHODS

Over a period of 2 years, 34 patients with clinical VT (of which 14 showed no post-infarction scarring) were treated with radiofrequency ablation. In 3 patients a percutaneous epicardial approach was indicated since prior attempts at conventional endocardial ablation had failed. Table 1 shows the characteristics of these 3 patients. Patients 1 and 3 showed frequent, non-sustained ventricular tachycardia and monomorphic ventricular extrasystoles (practically incessant at rest and sustained during exertion; Figure 1). Patient 2 showed sustained monomorphic ventricular tachycardia (SMVT) during exercise (Figure 1). Prior to the epicardial procedure, the 3 patients were examined in the electrophysiology laboratory (after giving their signed, informed consent). Their anti-arrhythmia me-
dication was suspended 5 half-lives before testing. Attempts were made to induce VT by programmed, basal, ventricular stimulation, and after the administration of isoproterenol.

Transient success was obtained in all 3 patients during endocardial radiofrequency ablation using irrigated-tip catheters. However, after a period ranging from a few minutes to a few days, arrhythmia reappeared in all cases. Pericardial puncture was necessary in patients 1 and 2. This was performed using a needle 69.85 mm (2.75") in length, via which a guidewire (diameter 0.97 mm; 0.038") was introduced. The latter allowed an 8F introducer to be positioned directly—a change of guidewire is necessary when epidural needles are used. The remainder of the procedure has been previously described. In patient 3, the epicardial procedure was performed via a left posterior coronary vein belonging to the coronary sinus branch. Endocardial and epicardial mapping was performed using the CARTO system (Biosense, Webster). In patients 1 and 2, 7 F catheters with irrigated tips were used. Radiofrequency ablation lesions were induced at a power of 30-35 Watts, maintaining a temperature of 50°C. In patient 3, a 5F ablation catheter (Medtronic) was used since the small caliber of the vein precluded access with an irrigated-tip catheter. In this case, the temperature was maintained at 60°C. Simultaneous coronary angiography was performed in all patients to avoid inducing ablation lesions in the coronary arteries. Following the procedure, the patients were treated with acetylsalicylic acid for 2 months. All patients underwent an echocardiogram, Holter monitoring and a stress test at 1, 3, and 6 months after the procedure.

**RESULTS**

The VT mechanisms of all the patients were compatible with trigger activity: they were induced (although with poor reproducibility) after the infusion of isoprenaline, and with bursts of extrastimuli rather than single extrastimuli. The stimulation maneuvers showed re-entry not to be the mechanism of tachycardia. Epicardial pace-mapping was performed in all 3
patients during sinus rhythm, which reproduced the 12-lead electrocardiograms of clinical VT, although high stimulus output energies were required (10-15 V×2 ms). In all 3 patients, earlier local electrograms (with respect to the QRS complex in VT) were achieved than with the prior endocardial procedure (Table 1). Before radiofrequency ablation, none of the patients showed abnormal endocardial potentials in terms of duration or voltage. Coronary angiography showed patients 2 and 3 to have normal coronary arteries. Patient 1 had a 70% lesion in a poorly developed circumflex artery. This was not treated since it was believed to play no role in the etiopathology of the VT. In no case was it necessary to undertake ablation at less than 5 mm from an important coronary artery. Patient 2 underwent right ventriculography, magnetic resonance and right ventricular biopsy in order to exclude arrhythmogenic dysplasia. The endocardium and epicardium of the right ventricular outflow tract (Figures 1 and 2), the left ventricular outflow tract and the aortic root were unsuccessfully mapped in this patient. In patient 3, venography of the coronary sinus was performed. In all patients, VT similar to the clinical form was induced during the epicardial ablation procedure. No complications arose in any patient, although all referred to non-specific precordial discomfort after the procedure. At 24 h the patients’ echocardiograms were normal and no pericardial rubbing was heard. No patient showed any sign of recurrence at one year of follow-up, and in patients 1 and 3 the left ventricular ejection fraction had normalized.

DISCUSSION

Conventional endocardial ablation failed to resolve the VT of these three patients, but the described epicardial approach was successful. The recent literature reports a number of small groups of patients to have been successfully treated in this manner.6-11 The novelty of the present report lies in the fact that, in patient 2, the tachycardia originated in the right ventricular outflow tract. The shape of the QRS complex of this patient during VT coincided with some features recently

performed by Schweiker et al,\textsuperscript{10} the VT of 9 of the 30
inferior area close to the mitral annulus. In the study
the VT circuit was in the epicardium in the posterio-
approach the only one possible. In the other 2 patients,
ventricular outflow tract, thus rendering an epicardial
gion joining the septum to the anterior wall of the right
part of the VT circuit may have fallen within the re-
regions is probably no greater than 1 cm. Alternatively,
that the lesions produced by the radiofrequency abla-
outflow tract, or even from the aortic root, suggests
be abolished from the endocardium of the right or left
route.

In patient 2, the reason why tachycardia could not
be abolished from the endocardium of the right or left
outflow tract, or even from the aortic root, suggests
that the lesions produced by the radiofrequency abla-
procedure where not transmural. This, however,
does seem rather strange since the thickness of these
regions is probably no greater than 1 cm. Alternatively,
part of the VT circuit may have fallen within the re-
gion joining the septum to the anterior wall of the right
ventricular outflow tract, thus rendering an epicardial
approach the only one possible. In the other 2 patients,
the VT circuit was in the epicardium in the posterior-
inferior area close to the mitral annulus. In the study
performed by Schweiker et al,\textsuperscript{10} the VT of 9 of the 30
patients was abolished by ablation in regions close and
either anterolateral or posterolateral to the mitral an-
nu. However, although one patient presented with di-
lated cardiomyopathy, the authors did not report
whether ventricular function improved after ablation.
In the present study, patients 1 and 3 had frequent
(practically incessant), non-sustained, monomorphic
tachycardia. Both showed left ventricular dysfunction of
no other possible cause than VT, and improved
spectacularly after the ablation procedure. In our opi-
nion, epicardial radiofrequency ablation should be
considered in patients with ventricular dysfunction and
very frequent monomorphic arrhythmias (especially if
there is no other cause to justify such dysfunction),
since the risks associated with the procedure are rela-
tively small and the benefit that might be gained is
great.

In the epicardial approach, ablation occurs close to
the coronary arteries. Recent studies suggest this pre-
sents no complications.\textsuperscript{3} However, none of the present
patients required ablation be performed within 1 cm of
these arteries. The use of an irrigated-tip might in-
crease the risk of damaging these vessels.

In conclusion, epicardial radiofrequency ablation
can be curative and should therefore be attempted in
patients with VT (but without heart disease) when the
endocardial approach fails.\textsuperscript{3} It should even be at-
tempted if the point of origin of the tachycardia lies
within the right ventricular outflow tract. A diagnosis
of tachycardiomyopathy should be considered for pa-
ents who present with dilated cardiomyopathy or
very frequent, non-sustained, monomorphic VT, since
ablation treatment can lead to the normalization of
ventricular function.
