The presence of diabetes mellitus worsens prognosis in acute coronary syndromes. The aim of our study was to analyze retrospectively the influence of diabetes mellitus on the management and prognosis of patients with non-ST-segment elevation acute coronary syndrome. We compared the baseline clinical characteristics of 273 patients (93 diabetic and 180 non-diabetic) admitted consecutively to our department with the diagnosis of non-ST-segment elevation acute coronary syndrome. In both groups, we assessed the medical treatment given during hospitalization and the use of coronary angiography, percutaneous coronary intervention, and coronary artery bypass grafting. Finally, we determined the incidence of heart failure during hospitalization and mortality at 28 days and 6 months in both groups. Multifactorial analysis revealed that diabetes was an independent risk factor for mortality during the study period. Data from our registry indicate that these findings were not associated with more extensive use of interventions in diabetic patients.

Key words: Unstable angina. Diabetes mellitus. Prognosis.

INTRODUCTION

In recent years, the definition of acute coronary syndrome (ACS), formulated parallel to the development of diagnostic and therapeutic advances of considerable clinical impact, has included the various forms of acute ischemic heart disease. In particular, in the last decade non-ST-elevation acute coronary syndrome (NSTEACS) and its prognostic stratification has raised interest among the various scientific societies. In the last decade, even with the current therapeutic possibilities, however, NSTEACS still presents high morbidity and mortality.

Diabetes mellitus (DM), one of the most prevalent diseases, is intrinsically linked to the development of arteriosclerosis and cardiovascular disease. There is abundant evidence to sustain that the prognosis of ACS among diabetic patients is poorer than among nondiabetics. The current epidemiology of DM in...
Spain readily explains the growing interest of the cardiologic community in the association between DM and cardiovascular disease.

The purpose of our study was to analyze the influence of DM on the prognosis and the clinical and therapeutic approach toward patients with NSTEACS.

METHODS

Study Population and Design

A historical cohort study was conducted with 273 patients (204 men and 69 women) admitted to our hospital from January 2001 to December 2002 with a diagnosis of NSTEACS according to published criteria. Among the total study population, 93 patients (34.1%) had DM versus 180 who were not diabetics. The patients were classified as diabetics if they had been diagnosed with DM, were receiving hypoglycemic therapy, or presented repeatedly high baseline blood sugar levels (>126 mg/dL in at least 2 fasting measurements) during admission. Among the 273 patients, 45.4% were on insulin therapy, 37.1% were receiving oral antidiabetic therapy, and 19.5% were managed by diet.

Data Analyzed

The following variables were collected in both groups: age, sex, history of cardiovascular risk factors (hypertension, dyslipidemia, and smoking), history of ischemic heart disease, drug therapy received, coronary angiography, and revascularization therapy (percutaneous or surgical) during the hospitalization. Lastly, we analyzed the onset of major cardiovascular events, defined as heart failure during admission and cardiovascular mortality at 28 days and at 6 months. This information was obtained by a review of the medical histories, personal interviews, and a phone survey of the patients.

Statistical Analysis

SPSS (Statistical Package for Social Sciences, version 10.0 for Windows) was used for the data analysis. The quantitative variables are expressed as mean±SD and the qualitative variables as percentages. The χ² test was used to compare the qualitative variables. Quantitative variables were compared using the Student’s t test. Cox proportional-hazards regression models were used to estimate the hazard ratio of clinical variables significantly different in the single-factor analysis (hypertension, dyslipidemia, smoker, history of myocardial infarction, and use of angiotensin-converting enzyme inhibitors [ACE inhibitors]).

RESULTS

The baseline characteristics of the patient population are shown in Table 1. There were no differences in age or sex between the 2 groups. In contrast, diabetic patients presented a higher prevalence of hypertension, dyslipidemia, previous myocardial infarction, and, paradoxically, smoking. Coronary angiography, percutaneous transluminal coronary angioplasty, and coronary bypass surgery was similar in the 2 groups, as is shown in Table 1.

Both groups had similar characteristics with regards to beta-blocker, acetylsalicylic acid, clopidogrel, heparin, and statin therapy during the hospitalization and follow-up phases. However, ACE inhibitors were more commonly used among diabetics (60% vs 37%; P<0.05).

With regard to the onset of major cardiovascular events, a higher incidence of heart failure during admission and a higher cumulative incidence of cardiovascular mortality at 28 days and at 6 months was found among the patients with DM (Table 2). The multivariate analysis showed that DM was an independent predictor of mortality (hazard ratio 3.4).

*DM indicates diabetes mellitus.
In any case, DM and those of the Sociedad we found that there was more invasive than among the nondiabetics.

In our study, diabetic patients had a higher prevalence of other cardiovascular risk factors and previous coronary artery disease than nondiabetics, a finding consistent with recent studies, except for smoking, which was generally lower in the diabetic population. In any case, DM per se is independently associated with a higher risk and poorer prognosis after ACS. In this regard, scientific associations such as the American Heart Association have gone on to consider it an “equivalent” of cardiovascular disease rather than merely a risk factor. Therefore, diabetic patients who have not experienced an ACS have the same risk of presenting it as nondiabetics who have had it previously.

In our study, at least the pharmacologic treatment used for NSTEACS was similar in both groups, except for ACE inhibitors, which were used most frequently among diabetic patients. Other authors have obtained similar findings. Despite the published recommendations, we observed that clopidogrel is not routinely utilized in NSTEACS and our diabetic population (at greater risk) also fails to benefit differentially from greater use of this agent. Consistent with other authors, we found that there were no significant differences between the study groups in the use of invasive strategies (interventional procedures and coronary bypass surgery).

In our study, heart failure during admission was more frequent among the diabetics. Diabetes mellitus and heart failure have been related to extensive coronary artery disease, autonomic dysfunction, and a high prevalence of hypertension. Likewise, the higher mortality observed among our diabetic patients could be due to a higher prevalence of hypertension and previous coronary artery disease. However, multivariate analysis maintained DM as an independent predictor of mortality.

Consequently, we feel that DM should prompt a different risk stratification after NSTEACS than that of a non-diabetic patient. Considering NSTEACS a high-risk event is a determining factor in deciding on an invasive therapeutic approach, clearly superior in general terms to a conservative approach (with results that can be extrapolated to the diabetic population, although noticeably lower). According to the European Society of Cardiology guidelines, the mere presence of DM is a high risk in NSTEACS, regardless of the presence of other high-risk criteria (clinical, electrocardiographic, or biochemical). In contrast, of the U.S. guidelines and those of the Sociedad Española de Cardiología (Spanish Society of Cardiology) propose that DM per se determines an intermediate risk.

**Limitations of the Study**

This is a single-center, retrospective study with all the limitations inherent to this kind of design. In initiating the new therapeutic recommendations for ACS were published around the time of the study period and may explain the sub-optimal use of some of the therapeutic strategies, now clearly defined for ACS.

**CONCLUSIONS**

Our study demonstrates that DM confers a special risk status among patients with NSTEACS and we believe that it is possible to optimize treatment for this large subgroup of patients. The decisive findings of epidemiological studies and projections on DM and its cardiovascular impact might indicate the need to adopt more interventional strategies for the treatment of ACS among the diabetic population, thus contributing in part to improve their prognosis following NSTEACS.
