INTRODUCTION

In recent years, the definition of acute coronary syndrome (ACS), formulated parallel to the development of diagnostic and therapeutic advances of considerable clinical impact, has included the various forms of acute ischemic heart disease. In particular, in the last decade non-ST-elevation acute coronary syndrome (NSTEMI) and its prognostic stratification has raised interest among the various scientific societies in the past decade. Even with the current therapeutic possibilities, however, NSTEMI still presents high mortality and morbidity. Diabetes mellitus (DM), one of the most prevalent diseases, is intrinsically linked to the development of arteriosclerosis and cardiovascular disease. There is abundant evidence to sustain that the prognosis of ACS among diabetic patients is poorer than among nondiabetics. The current epidemiology of DM in

BRIEF REPORT

Influence of Diabetes Mellitus on the Management and Prognosis of Non-ST-Elevation Acute Coronary Syndrome

The presence of diabetes mellitus worsens prognosis in acute coronary syndromes. The aim of our study was to analyze retrospectively the influence of diabetes mellitus on the management and prognosis of patients with non-ST-segment elevation acute coronary syndrome. We compared the baseline clinical characteristics of 273 patients (93 diabetic and 180 non-diabetic) admitted consecutively to our department with the diagnosis of non-ST-segment elevation acute coronary syndrome. In both groups, we assessed the medical treatment given during hospitalization and the use of coronary angiography, percutaneous coronary intervention, and coronary artery bypass grafting. Finally, we determined the incidence of heart failure during hospitalization and mortality at 28 days and 6 months in both groups. Multifactorial analysis revealed that diabetes was an independent risk factor for mortality during the study period. Data from our registry indicate that these findings were not associated with more extensive use of interventions in diabetic patients.

Key words: Unstable angina. Diabetes mellitus. Prognosis.

Influencia de la diabetes mellitus en el tratamiento y el pronóstico del síndrome coronario agudo sin elevación del segmento ST

La diabetes mellitus condiciona un peor pronóstico del síndrome coronario agudo. Presentamos un estudio retrospectivo cuyo objetivo fue analizar la influencia de la presencia de diabetes en el pronóstico y el tratamiento de pacientes con síndrome coronario agudo sin elevación del segmento ST. Se compararon las características clínicas de 273 pacientes (93 pacientes diabéticos frente a 180 no diabéticos) ingresados en nuestro centro con el diagnóstico de síndrome coronario agudo sin elevación del segmento ST. Durante la hospitalización analizamos en ambos grupos el tratamiento médico y la realización de coronariografía, intervencionismo y cirugía coronaria. Finalmente, analizamos la incidencia acumulada de insuficiencia cardíaca intrahospitalaria y la mortalidad a los 28 días y 6 meses en ambos grupos. El análisis multifactorial demostró que la diabetes fue un predictor independiente de mortalidad durante el período de seguimiento. Estos hallazgos no se acompañaron en nuestro registro de un tratamiento más intervencionista en el grupo de pacientes diabéticos.

Palabras clave: Angina inestable. Diabetes mellitus. Pronóstico.
Spain readily explains the growing interest of the cardiologic community in the association between DM and cardiovascular disease. 8,9 The purpose of our study was to analyze the influence of DM on the prognosis and the clinical and therapeutic approach toward patients with NSTEACS.

METHODS

Study Population and Design

A historical cohort study was conducted with 273 patients (204 men and 69 women) admitted to our hospital from January 2001 to December 2002 with a diagnosis of NSTEACS according to published criteria. 1-3 Among the total study population, 93 patients (34.1%) had DM versus 180 who were not diabetics. The patients were classified as diabetics if they had been diagnosed with DM, were receiving hypoglycemic therapy, or presented repeatedly high baseline blood sugar levels (>126 mg/dL in at least 2 fasting measurements) during admission. Among the group of diabetics, 43.4% were on insulin therapy, 37.1% were receiving oral antidiabetic therapy, and 19.5% were managed by diet.

Data Analyzed

The following variables were collected in both groups: age, sex, history of cardiovascular risk factors (hypertension, dyslipidemia, and smoking), history of ischemic heart disease, drug therapy received, coronary angiography, and revascularization therapy (percutaneous or surgical) during the hospitalization. Lastly, we analyzed the onset of major cardiovascular events, defined as heart failure during admission and cardiovascular mortality at 28 days and at 6 months. This information was obtained by a review of the medical histories, personal interviews, and a phone survey of the patients.

Statistical Analysis

SPSS (Statistical Package for Social Sciences, version 10.0 for Windows) was used for the data analysis. The quantitative variables are expressed as mean±SD and the qualitative variables as percentages. The χ2 test was used to compare the qualitative variables. Quantitative variables were compared using the Student’s t test. Cox proportional-hazards regression models were used to estimate the hazard ratio of clinical variables significantly different in the single-factor analysis 10 (hypertension, dyslipidemia, smoker, history of myocardial infarction, and use of angiotensin-converting enzyme inhibitors [ACE inhibitors]).

RESULTS

The baseline characteristics of the patient population are shown in Table 1. There were no differences in age or sex between the 2 groups. In contrast, diabetic patients presented a higher prevalence of hypertension, dyslipidemia, previous myocardial infarction, and, paradoxically, smoking. Coronary angiography, percutaneous transluminal coronary angioplasty, and coronary bypass surgery was similar in the 2 groups, as is shown in Table 1.

Both groups had similar characteristics with regards to beta-blocker, acetylsalicylic acid, clopidogrel, heparin, and statin therapy during the hospitalization and follow-up phases. However, ACE inhibitors were more commonly used among diabetics (60% vs 37%; P<0.05).

With regard to the onset of major cardiovascular events, a higher incidence of heart failure during admission and a higher cumulative incidence of cardiovascular mortality at 28 days and at 6 months was found among the patients with DM (Table 2). The multivariate analysis showed that DM was an independent predictor of mortality (hazard

artery disease, autonomic dysfunction, and a high

heart failure have been related to extensive coronary

frequent among the diabetics. Diabetes mellitus and

were no significant differences between the study

groups in the use of invasive strategies (interventional

procedures and coronary bypass surgery).

In our study, heart failure during admission was more

frequent among the diabetics. Diabetes mellitus and

heart failure have been related to extensive coronary

disease, autonomic dysfunction, and a high

prevalence of hypertension. Likewise, the higher

mortality observed among our diabetic patients could be
due to a higher prevalence of hypertension and previous

coronary artery disease. However, multivariate

analysis maintained DM as an independent predictor of

mortality.

Consequently, we feel that DM should prompt a
different risk stratification after NSTEACS than that of

a nondiabetic patient. Considering NSTEACS a high-
risk event is a determining factor in deciding on an

invasive therapeutic approach, clearly superior in
general terms to a conservative approach (with results

that can be extrapolated to the diabetic population,

although noticeably lower).

According to the European Society of Cardiology guidelines, the mere

presence of DM is a high risk in NSTEACS, regardless of the presence of other high-risk criteria (clinical, electrocardiographic, or biochemical). In contrast, of the U.S. guidelines and those of the Sociedad Española de Cardiología (Spanish Society of Cardiology) propose that DM per se determines an intermediate risk.

Limitations of the Study

This is a single-center, retrospective study with all the

limitations inherent to this kind of design. In initiation of

the new therapeutic recommendations for ACS were

published around the time of the study period and may

explain the sub-optimal use of some of the therapeutic

strategies, now clearly defined for ACS.

CONCLUSIONS

Our study demonstrates that DM confers a special

risk status among patients with NSTEACS and we

believe that it is possible to optimize treatment for this

large subgroup of patients. The decisive findings of

epidemiological studies and projections on DM and its

cardiovascular impact might indicate the need to adopt

more interventional strategies for the treatment of ACS

among the diabetic population, thus contributing in

part to improve their prognosis following NSTEACS.
